11.1-1.

Suppose that a dynamic set S is represented by a direct-address table T of length m. Describe a procedure that finds the maximum elements of S. What is the worst-case performance of your procedure?

Answer.

As the dynamic set S is represented by the direct-address table T, for each key k in S, there is a slot k in T points to it. If no element with key k in S, then T[k]=NIL. Using this property, we can find the maximum element of S by traversing down from the highest slot to seek the first non-NIL one.

```
\begin{split} & \operatorname{Maximum}(S) \\ & 1 \quad \mathbf{return} \ \operatorname{Table-Maximum}(T,m-1) \\ & \operatorname{Table-Maximum}(T,l) \\ & 1 \quad \mathbf{if} \ l < 0 \\ & 2 \quad \mathbf{return} \ \operatorname{NIL} \\ & 3 \quad \mathbf{elseif} \ \operatorname{Direct-Address-Search}(T,l) \neq \operatorname{NIL} \\ & 4 \quad \mathbf{return} \ l \\ & 5 \quad \mathbf{else} \ \mathbf{return} \ \operatorname{Table-Maximum}(T,l-1) \end{split}
```

The Table-Maximum procedure goes down and checks 1 slot at a time, linearly approaches the solution. In the worst case where S is empty, Table-Maximum examines m slots. Therefore, the worst-case performance of Maximum is O(n), where n is the number of elements in the set S.
